## Abstract

**Background** Variation persists in the quality of end-of-life-care (EOLC) for people with cancer. This study aims to describe the characteristics of, and examine factors associated with, indicators of potentially burdensome care provided in hospital, and use of hospital services in the last 12 months of life for people who had a death from cancer.

**Method** A population-based retrospective cohort study of people aged  $\geq 20$  years who died with a cancer-related cause of death during 2014–2019 in New South Wales, Australia using linked hospital, cancer registry and mortality records. Ten indicators of potentially burdensome care were examined. Multinomial logistic regression examined predictors of a composite measure of potentially burdensome care, consisting of  $> 1$  ED presentation or  $> 1$  hospital admission or  $\geq 1$  ICU admission within 30 days of death, or died in acute care.

**Results** Of the 80,005 cancer-related deaths, 86.9% were hospitalised in the 12 months prior to death. Fifteen percent had  $> 1$  ED presentation, 9.9% had  $> 1$  hospital admission, 8.6% spent  $\geq 14$  days in hospital, 3.6% had  $\geq 1$  intensive care unit admission, and 1.2% received mechanical ventilation on  $\geq 1$  occasion in the last 30 days of life. Seventeen percent died in acute care. The potentially burdensome care composite measure identified 20.0% had 1 indicator, and 10.9% had  $\geq 2$  indicators of potentially burdensome care. Compared to having no indicators of potentially burdensome care, people who smoked, lived in rural areas, were most socially economically disadvantaged, and had their last admission in a private hospital were more likely to experience potentially burdensome care. Older people ( $\geq 55$  years), females, people with 1 or  $\geq 2$  Charlson comorbidities, people with neurological cancers, and people who died in 2018–2019 were less likely to experience potentially burdensome care. Compared to people with head and neck cancer, people with all cancer types (except breast and neurological) were more likely to experience  $\geq 2$  indicators of potentially burdensome care versus none.

**Conclusion** This study shows the challenge of delivering health services at end-of-life. Opportunities to address potentially burdensome EOLC could involve taking a person-centric approach to integrate oncology and palliative care around individual needs and preferences.

**Keywords** End-of-life-care, Health care utilisation, Palliative care, Cancer

## Introduction

Cancer is one of the leading causes of death internationally [1], and in Australia, around 151,000 people are newly diagnosed with cancer each year, with an estimated 1.3 million cancer-related hospital admissions [2]. Cancer-related morbidity and mortality is predicted to increase due to an ageing and increasing population [3–5]. This will create challenges for the provision of cancer management, including end-of-life-care (EOLC) [3]. Due to differing approaches to EOLC management, EOLC can be complex to navigate and also to evaluate [6]. Availability of hospital, palliative or hospice services, resources, level of community support, and both patient and clinical characteristics can all influence the quality of EOLC [7, 8].

Towards the end-of-life (EOL), there may be an increase in hospital-based care to actively address potentially reversible conditions (e.g. infections) or at points where the person's prognosis may be uncertain. Some people experiencing cancer, however, may undergo care that could be viewed as 'potentially burdensome' in their last few weeks of life (e.g. multiple hospital or intensive care unit (ICU) admissions, or intravenous (IV) chemotherapy in last 2 weeks of life) that could negatively impact on their quality of life [6, 9, 10]. This sort of potentially burdensome care aimed at prolonging life can sometimes prevail over more comfort-based care [9, 10], and can reduce the amount of time that people spend in their preferred place at their EOL, which is often their home [11]. However, the majority of cancer patients die in health facilities [12]. Previous research identified that 18% of people with cancer (up to 65% if deaths in acute care are included) in Switzerland [7], 22% in Canada [13], 30% in the United States (US) [14], and 34% in the Netherlands [9] experienced at least one indicator of potentially burdensome care at the EOL.

Variation in the quality of EOLC is notable and remains an area where healthcare improvements could be explored [6, 15]. Potentially burdensome EOLC can be costly [16], and not add benefit to a cancer patient's EOL quality [9]. Indicators of potentially burdensome care towards the EOL for people with advanced cancer have been recommended in prior literature and can be derived from population-based administrative data collections [7, 14, 17, 18] which can provide a cost-effective method of identifying potential variation in EOLC, but have not been extensively examined in Australia. Examination of hospital-based EOLC quality indicators in Australia could pinpoint variation in care delivered at the EOL for people with cancer and indicate opportunities for EOLC quality improvement measures. It may also identify opportunities where EOLC could be enhanced, with the potential to reduce any unnecessary hospital visits, and enhance 24-hour home-based palliative care and home

care services. This study aims to describe the characteristics of, and examine factors associated with, indicators of potentially burdensome care provided in hospital and use of hospital services in the last 12 months of life for people who had a death from cancer in New South Wales (NSW), Australia.

## Method

This is a retrospective cohort study of people who had a death from cancer in NSW, Australia, during 1 January 2014 to 31 December 2019. Mortality data was linked to hospital and cancer registry records for 365 days prior to the date of death.

### Data sources and linkage

Mortality data were obtained from the NSW Registry of Births, Deaths and Marriages and the cause of death unit record file (COD-URF) and included date of death and underlying and up to 20 antecedent causes of death. Cause of death was classified using the International Classification of Diseases, 10th Revision (ICD-10). The NSW Cancer Registry records notifications of people with cancer in NSW (except for non-melanoma skin cancer) and includes information on demographics, diagnosis date, cancer type and degree of spread, place of death, and cause of death. NSW Cancer Registry records were provided from 1972 to 2019 to identify diagnosis date and previous history of cancer.

Hospital records were obtained for non-admitted patient occasions of service (i.e. outpatients), emergency department (ED) presentations, and hospital admissions in NSW. Non-admitted patient records included clinical or therapeutic services provided by NSW Health that warrant a note regarding the service being included in the client's medical record. The non-admitted patient dataset was available as a calendar year from 1 January 2016 and includes public hospitals and information on client demographics, type of service, type of service contact (e.g. in-person, videoconference) and service provider. Non-admitted patient data where there was no client contact were excluded from service counts.

ED presentations to public hospitals in NSW included information on arrival and departure times, visit types and separation type. Hospital admissions were to all public and private hospitals, and information available included principal and additional diagnoses, clinical procedures, and separation type (e.g. hospital transfer, death). Diagnoses were classified using the International Classification of Diseases, 10th Revision Australian-modification (ICD-10-AM). Country of birth was identified using the Standard Australian Classification of Countries [19] in the hospital records and was categorised as Australia and other countries.

The data sources were linked by the Centre for Health Record Linkage (CHeReL) using probabilistic linkage. Upper and lower probability cut-offs for a link were 0.75 and 0.25 and record groups with probabilities between the cut-offs were clerically reviewed.

### Case inclusion criteria

Cases included individuals aged  $\geq 20$  years with a cancer-related cause of death (ICD-10: C00-C96, D45, D46, D47.1, D47.3-D47.5) in their underlying cause of death in the COD-URF during 2014–2019. Cancer type was identified using cause of death records (Supplementary Table S1). There were  $n=15,020$  deaths excluded from analysis as the underlying cause of death was not recorded as cancer, but cancer was identified in any of 20 antecedent causes of death. Also excluded were  $n=1,340$  deaths from non-melanoma skin cancer (ICD-10: C44) and individuals that died within 30 days of diagnosis ( $n=9,609$ ). The hospital service use of individuals who received a non-admitted patient service or who had an ED presentation or a hospital admission and separation within 365 days of their date of death were examined. There were  $n=2,392$  (3.0%) individuals who had a hospital separation during the 365 days before death, but their hospital admission was pre-365 days before death, and these individuals were included in the analysis of hospital service use.

**Table 1** EOLC indicators of potentially burdensome care and potentially adequate symptom management

Indicator	Definition	Source
Potentially burdensome care at EOL in hospital		
A	> 1 ED visit in last 30 days of life	[6, 7, 13, 14, 24, 26]
B	> 1 hospitalisation in last 30 days of life (excluding palliative or hospice care)	[6, 7, 13, 24, 26]
C	Admission to ICU in last 30 days of life	[6, 7, 13, 14, 18, 24–28]
D	Place of death at EOL was in acute care (excluding palliative or hospice care)	[7, 14, 25]
E	Spending $\geq 14$ days in hospital in last 30 days of life (excluding palliative or hospice care)	[14]
F	$\geq 3$ hospitalisations in last 90 days of life (excluding palliative or hospice care)	[7]
G	Mechanical ventilation in last 30 days of life	[18, 27]
H	Radiotherapy in last 30 days of life	[36]
I	New IV chemotherapy commencing in last 30 days of life	[7, 14, 18, 27, 36]
J	Last dose IV chemotherapy in last 14 days of life	[6, 7, 13, 14, 24, 26]
K	Last dose IV chemotherapy in last 7 days of life	<sup>1</sup>

<sup>1</sup> Personal communication, Liauw W, 22 April 2022

### Residents of aged care and place of death

Patients who were living in residential age care during their last hospital admission before their death were identified using any one or a combination of data from hospital records, including separation mode, source of referral, and financial class (i.e. visit payment). Death in acute care was identified using admission and separation dates, date of death and separation mode (i.e., died) in hospital admission records. Death in the ED was identified using separation mode. Where the individual had not used hospital services, location of death was identified using place of death recorded in the NSW Cancer Registry.

### Palliative or hospice care

Palliative or hospice care was identified using any one or a combination of data items in hospital admission records that indicated palliative or hospice care (i.e. episode of care type, service-related group, unit type on admission, peer-group, facility type, separation mode) or an additional diagnosis in up to 50 diagnosis codes of palliative care (ICD-10-AM: Z51.5) [20].

### ICU admissions and mechanical ventilation

Hospital admission records identify hours in an intensive care unit (ICU) and hours were categorised as ICU admission (Y/N). Likewise, hours on mechanical ventilation are recorded in hospitalisation records and categorised as mechanical ventilation (Y/N).

### EOLC indicators

Eleven indicators of potentially burdensome care at EOL were identified from the literature and expert opinion (Table 1). One identified EOLC indicator of ‘new’ chemotherapy episodes was not able to be identified using the available data. In line with earlier studies, a composite measure of potentially burdensome care was defined using four of the ten indicators as at least one occurrence of either: (i) > 1 ED presentation within 30 days of death; or (ii) > 1 hospital admission within 30 days of death; or (iii)  $\geq 1$  ICU admission within 30 days of death; or (iv) died in acute care hospital – all excluding palliative/hospice care [6, 17]. Patients were categorised as experiencing none, 1 indicator, or  $\geq 2$  indicators of potentially burdensome care [6, 17].

### Identification of comorbidities

The Charlson Comorbidity Index was used to identify comorbidities using up to 50 diagnosis classifications in hospitalisation records [21]. A one-year lookback was applied from the date of death to identify comorbidities in the hospital admission data (i.e. to 1 January 2013). Charlson comorbidities, excluding malignancies, were categorised as nil, 1 and  $\geq 2$  comorbidities. Comorbid conditions related to depression (ICD-10-AM: F20.4,

F31.3, F31.4, F31.5, F32, F33, F34.1, F41.2, F43.2), anxiety-related disorders (ICD-10-AM: F40-F48), alcohol misuse and dependence (ICD-10-AM: F10, Y90, Y91, Z50.2, Z71.4, Z72.1), drug-related dependence (ICD-10-AM: F11-F16, F19, Z50.3, Z71.5, Z72.2), and tobacco use (ICD-10-AM: F17.0-F17.9, P04.2, T65.2, Z58.7, Z71.6, Z72.0, Z81.2, Z86.43) were also identified using hospital records.

### Socio-economic status and geographic location

An indicator of socio-economic disadvantage was assigned using the index of relative socioeconomic disadvantage [22] and Statistical Area Level 2 (SA2) of residence in hospital or NSW Cancer Registry records. The values were partitioned into quintiles from most (i.e. 1) to least disadvantaged (i.e. 5). The quintiles are derived from Australia's population census using information including education, employment, occupation and income. The Australian Statistical Geographical Standard Remoteness Area [23] and SA2 of residence in hospital records or NSW Cancer Registry records was used to derive the five remoteness categories, based on distance to service centres. These categories were collapsed into: urban (i.e. major cities) and rural (i.e. inner regional, outer regional, remote, and very remote).

### Chemotherapy and radiotherapy

Chemotherapy administered in hospital was identified using a principal diagnosis of cancer (ICD-10-AM: C00-C96, D45, D46, D47.1, D47.3-D47.5) and the principal or up to 50 additional procedure block codes indicating 'administration of pharmacotherapy' (1920) or 'other procedures related to pharmacotherapy' (1922) [2] or an Australian-refined diagnosis related group (AR-DRG) of chemotherapy (R63Z). IV chemotherapy or radiotherapy administered via outpatients was identified using the non-admitted patient data collection service type and service classification of chemotherapy or radiotherapy, respectively.

### Data management and analysis

Data were analysed using SAS 9.4 (SAS Institute, Cary NC). All hospital episodes of care related to the same event were linked to form a period of care. Descriptive analysis was used to describe the number of non-admitted patient services, ED presentations and hospital admissions in the last 12 months prior to death. Chi-square tests of independence, one-way ANOVA or Kruskal-Wallis Test, as appropriate, were used to examine the characteristics of individuals who received none, 1 or  $\geq 2$  indicators of potentially burdensome care at EOL.

Multivariable, multinomial logistic regression was used to examine predictors of indicators of potentially burdensome care. Variables included in the model were

identified from the literature [6, 7, 13, 14, 18, 24–28] and available in the data, and included age at death, sex, cancer type, cancer degree of spread, history of other cancer, count of Charlson comorbidities (excluding malignancies) (i.e. 0, 1,  $\geq 2$  comorbidities), depression, anxiety, tobacco use, alcohol or drug dependence, survival duration from date of diagnosis during the study timeframe to date of death (i.e. 31–89 days,  $\geq 90$  days to  $< 180$  days,  $\geq 180$  days), urban/rural residence, socioeconomic status, year of death, and public/private hospital at last admission prior to date of death. A backwards stepwise regression sequentially eliminated factors from the model that did not significantly contribute to risk of burdensome care at a significance level of  $p < 0.05$  that were screened at  $\leq 0.2$  in univariable analysis [29] (i.e. cancer degree of spread, depression, and drug-related dependence). Odds ratios (OR) and 95% confidence intervals (CIs) were calculated.

Predictors associated with each of the 11 indicators of potentially burdensome EOLC were also examined individually using multivariable logistic regression (Supplementary Figure S1a and S1b). Variables included in the models were the same as for the multinomial logistic regression and a backwards stepwise regression sequentially eliminated factors at  $p < 0.05$ , that were screened a significance level at  $\leq 0.2$  in univariable analysis [29]. ORs and 95% CIs were calculated.

### Results

There were 80,005 cancer deaths in NSW identified in the COD-URF during the seven year period. Of these, 3,013 (3.8%) deaths were either not reported or did not link to a record in the NSW Cancer Registry. Of the 80,005 decedents, 86.9% were hospitalised in the 12 months prior to death. The proportion of people hospitalised were lowest in the 12 months before death (41.3% including palliative care and 60.0% not including palliative care) and highest in the month before death (86.9% including palliative care and 86.7% excluding palliative care) (Fig. 1). The most common cancer types were lung (18.1%), digestive organs (excluding colorectal) (17.0%), colorectal (11.8%), and blood and lymphatic system (11.4%).

For the decedents in their last 30 days of life, 14.8% had  $> 1$  ED presentation, 9.9% had  $> 1$  hospital admission, 3.6% had  $\geq 1$  ICU admission, and 1.2% had  $\geq 1$  mechanical ventilation – all excluding palliative and hospice care. 17% of people died in acute care (and 52.7% died in hospital including non-acute palliative and hospice care), 8.6% had  $\geq 14$  days spent in hospital in the last 30 days of life, and 18.2% had  $\geq 3$  hospital admissions in the last 90 days of life. Demographic, cancer and clinical characteristics varied by indicator type (Supplementary Tables S2 and S3). In the year before death, there was an increase in the mean number of hospital admissions excluding

**Fig. 1** Proportion of decedents hospitalised by month in last 12 months of life

palliative care (from 0.8 to 3.1 admissions per month), hospital admissions including palliative care (0.8 to 4.6) and ED presentations (0.7 to 3.1) (Supplementary Figure S2).

There were 53,523 decedents during 2016 to 2019 where non-admitted patient data was available. Of these, 3.5% and 7.3% had a dose of chemotherapy in their last 7 days and 14 days of life, respectively, and 5.7% received radiotherapy in their last 30 days of life. Demographic characteristics of decedents varied by indicator type (Supplementary Table S4). Radiotherapy within the last 30 days of life was most commonly provided to people with lung cancer (33.0%). IV chemotherapy within the last 7 and 14 days of life was most commonly administered to people with lung cancer (21.3% and 21.0%, respectively), cancers of the blood and lymphatic system (17.5% and 18.1%, respectively), and cancers of the digestive organs, excluding colorectal cancer (16.6% and 16.3%, respectively) (Supplementary Table S5). In the last 12 months of life, the mean number of non-admitted patient occasions of service (after excluding non-client contacts) increased from 11.7 to 49.9 per month (Supplementary Figure S3).

The potentially burdensome care composite measure identified that 69.2% of decedents did not have any of the four indicators of potentially burdensome care, 20.0% had one indicator, and 10.9% had  $\geq 2$  indicators. People who had a higher proportion of 1 or  $\geq 2$  indicators of potentially burdensome care compared to none, were younger (20–54 year) (9.7% and 11.9% vs. 7.2%), male (59.6% and 62.6% vs. 54.8%), had no comorbidities (37.7% and 43.3% vs. 30.7%), were smokers (50.2% and 58.2% vs. 40.4%), and died in hospital (68.3% and 73.3% vs. 42.3%), respectively (Tables 2 and 3).

Compared to having no composite indicators of potentially burdensome care, people who smoked, lived in rural locations, were in the most disadvantaged socioeconomic group, and had their last admission before death in a private hospital were more likely to experience 1 or  $\geq 2$  indicators of potentially burdensome care than referent groups. The odds of experiencing  $\geq 2$  indicators of potentially burdensome care compared to none was lower for people with head and neck cancer, compared to people with each of the other cancer types except for breast and neurological cancers. The following subgroups were less likely to experience both 1 or  $\geq 2$  indicators of potentially burdensome care, compared to none: older people ( $\geq 55$  years), females, people with 1 or  $\geq 2$  Charlson comorbidities, people with neurological cancers, and people who died in 2018 or 2019 compared to referent groups (Fig. 2).

## Discussion

This study used linked mortality, hospital, and cancer registry records to examine indicators of potentially burdensome EOLC for people whose principal cause of death was cancer in the last 12 months of life. The proportion of decedents who used hospital services increased in the last months of life. The results indicate that between 1.2% and 18.2% of decedents met at least one of 11 indicators of potentially burdensome care in the last 12 months of life. Several characteristics, including people who smoked, lived in rural locations, were most socioeconomically disadvantaged, had certain cancer types, and who had their last admission in a private hospital, were associated with people experiencing 1 or  $\geq 2$  indicators of potentially burdensome care compared to none.

Potentially burdensome EOLC can result in poor quality of life [30] and signal challenges in integrated care coordination [7]. In the last 30 days of life, the current study identified that 14.8% of decedents had >1 ED presentation. The proportion of ED presentations identified was similar to Alberta, Canada (12.5%) [6], the

Netherlands (12% who had >2 ED visits) [9], Taiwan (18.3%), and Ontario, Canada, for people with advanced pancreatic cancer (18.5%) [24], but is seven times higher than Switzerland (2.1%) [7], and lower than Belgium (33.8%) [10]. Predictors associated with each of the seven indicators of potentially burdensome EOLC were

**Table 3** Cancer and clinical characteristics of the cancer decedents by potentially burdensome care composite index

<sup>1</sup> Not known excluded from the chi-square test of independence

generally similar, except for >1 ED visit in last 30 days of life, where people with a lower socioeconomic status had a higher likelihood of visiting the ED and were less likely to have their last hospital admission in a private hospital, both likely reflecting reduced access to other care options and lack of private health insurance, respectively.

The current study identified that for people with cancer in the last 30 days of life, 9.9% had >1 hospital admission, 8.6% spent ≥14 days in acute care, 3.6% had ≥1 ICU admission, and 1.2% had ≥1 mechanical ventilation. A range of factors including differing practices, resource availability, and patient demographic and clinical factors [31–33] are likely responsible for differences in EOLC

hospital service use for people with cancer reported in other countries in the last 30 days of life (Table 4). It is also possible that the use of ED and/or hospitalisation may be being used as a substitute for community-based palliative care [34], which would have implications for service design. In particular, private hospitals may be acting as a de-facto hospice, especially in regional areas. However, it should be acknowledged that lower rates of ED presentations or hospital admissions may not represent 'good' EOLC [32], but do potentially signal the challenges people living with advanced cancer at home experience accessing timely community based 24-hour cancer, palliative and/or primary care.

In the current study, the mean number of ED presentations, hospital admissions and non-admitted patient occasions of service increased in the last 12 months, as has been demonstrated elsewhere [31]. Fewer ED presentations near EOL has been flagged as a signal of the strength of integration of palliative and oncology services within acute care [35]. However, a rise in use of hospital

services towards the EOL is not unique to cancer [34]. It is also possible that some of the hospital service use within the 12-month EOL period were not related to cancer treatment but were for other causes.

In the current study, 17% of people died in acute care. This proportion compares similarly to Netherlands (20%) [9], but is less than half the proportion reported in other

countries, including Alberta, Canada, (50%) [6], Austria (53%) [36], Switzerland (56%) [7], and Taiwan (63%) [37]. Differences in the number of acute care deaths between countries could reflect the availability of 24 h home-based palliative care services or hospice beds [14], good symptom and pain management, adequate family support, and patient preferences regarding the location of their death and their families ability to support their wishes [11, 33].

Four percent of decedents had a dose of chemotherapy in their last 7 days of life and 7.3% had a dose in their last 14 days of life in the current study. Similar proportions of people with cancer received their last dose of chemotherapy within their last 7 and 14 days of life in Belgium (4% and 8.6%, respectively) [10], within their last 14 days of life in Switzerland (7%) [7] and in Ontario (7.1%) [24]. Almost double the proportion of people with cancer (15.7%) received chemotherapy within their last 14 days of life in the US [14], while a systematic review identified that between 1 and 19% of patients received chemotherapy in their last 14 days of life [32]. Chemotherapy provided near EOL may be of limited benefit and signal overuse [26, 38]. However, patient preferences also should be considered; previous research identified that patients who preferred life-extending care were likely to receive chemotherapy within 2 weeks of death compared to patients who preferred comfort-orientated care [39].

Within the current study, 5.7% of decedents received radiotherapy in their last 30 days of life. In comparison, in Austria, 1.7% of people with cancer received radiotherapy in 30 days before death [36]. While radiotherapy can assist in pain management for advanced cancer, its provision close to EOL is not likely to be efficacious [38].

There were 20% and 11% of decedents, respectively, in the current study that had 1 or  $\geq 2$  indicators of potentially burdensome EOLC. In the Netherlands, around one-third of cancer decedents experienced potentially burdensome EOLC in the 30 days before EOL [9]. In Switzerland, 23.8% of decedents had one and 40.4% had  $\geq 2$  indicators of potentially burdensome care [7]. The proportional variation in the presence of potentially burdensome indicators of EOL between countries may be attributable to differences in cohort inclusion criteria, the type of composite indicators included, and/or availability of palliative care services [40].

The current study identified that people who smoked, lived in rural locations, who were most socioeconomically disadvantaged were more likely to experience burdensome care, while older people ( $\geq 55$  years), females, people with comorbidities, were less likely to experience indicators of potentially burdensome care. Similarly, previous research also identified that people with comorbidities [6, 7], people who lived in rural locations [6], older

people and females were less likely to receive potentially burdensome treatment at EOL [6, 10, 14].

Use of palliative care has the potential to reduce potentially burdensome EOLC and pain [7, 24]. Within Australia, an estimated 42% of hospital-based palliative care was for patients with a principal diagnosis of cancer [41]. The provision of palliative care in the last 30 days of life has been associated with people with cancer being five times less likely to experience potentially burdensome EOLC [9]. Any treatment provided at EOL should have the potential to improve symptoms/comfort, be consistent with patient and family preferences [14], involve shared decision-making and consider cost-efficient resource utilisation by avoiding high-cost acute resources [39, 42].

There is scope for future research to examine predictors of potentially burdensome care by cancer type, geographic location, and also to consider indicators of the use of specialist oncology services and pharmaceutical use, such as opioid prescriptions, towards the EOL [10]. The timing of the use of palliative and hospice care, examining group-based trajectories of hospital service use at EOL, and further comparison between jurisdictions may aid to identify differing or similar care practices for sub-population groups. Predictive computer models, using machine learning, to better identify patients near their EOL using mortality prediction modelling may aid decision making of clinicians as well [43].

The strengths of the study include that it was population-based and included multiple linked data collections that enabled capture of hospital service use. The study considered all cancer types and all ages  $\geq 20$  years. As to limitations, the EOLC indicators provide an indication of the quality of healthcare services rather than the quality of care provided to individuals, therefore the absence of an EOLC indicator does not ensure the provision of good quality EOLC, as a person with cancer who died at home may not have had access to good community or home-based palliative care support [6]. Alternatively, the presence of an EOLC indicator does not mean a patient received poor quality care, as some acute care may be clinically warranted [9]. More granular data about the reason for admission and procedures administered would be able to provide insight as to whether treatment could be viewed as not burdensome to the individual. Further, it is not possible to predict exactly when a person with cancer may die, and some people may be admitted for curative treatment and die unexpectedly.

Whether the radiotherapy was single or multi-fraction external beam radiotherapy could not be identified – for treatment of bone metastases. NSW residents who lived near the borders of NSW whose death was recorded in NSW may have received hospital-based treatment interstate, and no information was available on their health service use. Under-enumeration of care is particularly

likely for people with cancer who received chemotherapy and radiotherapy interstate, as northern NSW residents often travel to Queensland, southern NSW residents to Victoria, and south-western NSW residents to South Australia to receive treatment [44]. These patients represent a small proportion of all NSW cancer patients. In the current study, no information was available regarding other health service use (e.g. primary care, palliative care and home care services), pharmaceutical prescriptions or advance care planning. There is likely under-enumeration of people with cancer who received palliative or hospice care and the identification of aged care residents in hospital records. Within hospital records, only comorbidities that had an impact on patient care are recorded, which is likely to result in under-enumeration of chronic health conditions. However, by using a one year look back period, better estimates of the prevalence of health conditions were likely able to be obtained in the current study [45]. Information on primary care was not available for this study, which may have included information on comorbidities. Hospital data validity was not able to be assessed. It is acknowledged that the potential burdensome indicators of EOLC focus on care provided in acute care, thus an individual who presented to ED only (and who was not admitted to hospital), would only have the potential to experience one potentially burdensome indicator of EOLC and would not have been exposed to other indicators considered for admitted patients only.

## Conclusion

This study identified that in last month of life, some cancer decedents experienced potentially burdensome treatments. It signals the challenge of health service delivery at the EOL and can provide a reference baseline for future work examining EOLC for people with cancer. There are likely opportunities to address any potentially burdensome EOLC by taking a person-centric approach and integrating oncology and palliative care around individual needs and preferences.

## Acknowledgements

The authors wish to thank the NSW Ministry of Health for providing access to the non-admitted patient data, ED visit, hospitalisation, and mortality data, NSW Cancer Institute for providing access to the NSW Cancer Registry, and the Centre for Health Record Linkage for conducting the data linkage. The authors acknowledge assistance from Dr R Walsan in creating forest plots in R.

## Author contributions

RM conceived the study concept and design. RM acquired and organised the data, conducted the analysis and wrote the first draft of the manuscript. All authors (i.e., RM, GD, GA, WL, JP, RL, RH, JB) were involved in interpretation of data and critical revision of the manuscript.

## Funding

This research was supported by an NHMRC Centre of Research Excellence in Implementation Science in Oncology (1135048, CI Braithwaite).

## Data availability

The data that support the findings of this study are available from the NSW Ministry of Health and the NSW Cancer Institute. Restrictions apply to the availability of these data, which were used under licence for the current study, so are not publicly available.

## Declarations

### Ethics approval and consent to participate

Ethical approval and a waiver of consent was obtained from the NSW Population and Health Services Research Ethics Committee (2022/ETH01228). The study was conducted in accordance with relevant guidelines and regulations.

### Consent for publication

Not applicable.

### Competing interests

The authors declare no competing interests.
